ABSTRACT

In this paper we present a novel source separation method aiming to overcome the difficulty of modelling non-stationary signals. The method can be applied to mixtures of musical instruments with frequency and/or amplitude modulation, e.g. typically caused by vibrato. The method is based on a signal representation, dividing the spectrogram into a grid of patches of arbitrary size. The patches are then transformed using a two-dimensional discrete Fourier transform, forming a tensor representation which reveals spectral and temporal modulation textures. Our representation can be seen as an alternative to modulation spectrograms. An adapted factorization model allows to decompose different time-varying harmonic sources based on their particular common modulation profile: hence the name Common Fate Model. The method is evaluated on musical instrument mixtures playing the same fundamental frequency (unison), showing improvement over other state-of-the-art methods.

Index Terms—Sound source separation, Common Fate Model, non-negative tensor factorization.

1. INTRODUCTION

Sound source separation continues to be a very active field of research [1] with a variety of applications. Many recent contributions are based on the popular non-negative matrix factorization (NMF). The way NMF factorizes a spectrogram matrix into frequency and activation templates makes it possible to easily design algorithms in an intuitive way. At the same time, it provides a rank reduction, needed to decompose mixtures into their source components. In the past, many NMF-based source separation methods have been developed [2,4]. Expanding the NMF to tensors allows us to incorporate more complex models, useful in many applications like multichannel separation. Extensions to NMF such as shift-invariance or convolutions were carried over to non-negative tensor (NTF) based algorithms [5,7]. These approaches, relying on decomposing mixtures of musical instruments, work well when certain assumptions hold to be true. One is that spectral harmonics only partially overlap. However, when two sources share the same fundamental frequency, almost all partials do overlap, making it difficult for NMF-based algorithms to learn unique templates. Another assumption is that all spectral and temporal templates semantically correspond to musical notes, forming a dictionary of musically meaningful atoms. This does not hold for instruments with time-varying fluctuations.

These effects can typically be found in musical instruments like strings and brass, when played with vibrato. In a setting where two musical instruments with vibrato play in unison, both assumptions could break, which makes it a challenging scenario [10]. When processing such mixtures with a representation based on a standard NMF and the magnitude spectrogram, it is hard to model the sources with only a few spectral templates. Instead of increasing the number of templates per source, Hennequin proposes [11] frequency-dependent activation matrices by using a source/filter-based model. Since the vibrato does not only cause frequency modulation (FM) but also amplitude modulation (AM), so-called modulation spectra can be used to identify the modulation pattern. This is often calculated by taking the Fourier transform of a magnitude spectrum. Thus, the modulation spectrogram has already gathered much attention in speech recognition [12,13] and classification [14,15]. Barker and Virtanen [16] were the first to propose a modulation tensor representation for single channel source separation. This allows to elegantly apply factorization on the tensor by using the well known PARAFAC/CP decomposition.

In this work we introduce a novel tensor signal representation which additionally exploits similarities in the frequency direction. We can therefore make use of dependencies between modulations of neighbouring bins. This is similar to the recently proposed High-Resolution Nonnegative Matrix Factorization model that accounts for dependencies in the time-frequency plane (HR-NMF [17]). In short, HR-NMF models each entry of a time-frequency transform of an audio signal as a linear combination of its neighbours, enabling the modelling of damped sinusoids, along with an independent innovation. This model was generalized to multichannel mixtures in [18,19] and was shown to provide considerably better oracle performance for source separation than alternative models in [20]. Indeed, even though some variational approximations were introduced in [21] to strongly reduce their complexity, those algorithms are often demanding for practical applications. In this paper, we propose to relax some assumptions of HR-NMF in the interest of simplifying the estimation procedure. The core idea is to divide the complex spectrogram into modulation patches in order to group common modulation in time and frequency direction. We call this the Common Fate Model (CFM), borrowing from the Gestalt theory, which describes how human perception merges objects that move together over time. Bregman [22] described the Common Fate theory for auditory scene analysis as the ability to group sound objects based on their common motion over time, as occurs with frequency modulations of harmonic partials. As outlined by Bregman, the human ability to detect and group sound sources by small differences in FM and AM is outstanding. Also, it turns out that humans are especially sensitive to modulation frequencies around 5 Hz, which is the typical vibrato frequency that many musicians produce naturally.

2. COMMON FATE MODELLING

2.1. The Common Fate Transform

Let \( \tilde{x} \) denote a single channel audio signal. Its Short-Term Fourier Transform (STFT) is computed by splitting it into overlapping frames, and then taking the discrete Fourier transform (DFT) of each one. The resulting information is gathered into an \( N_a \times N_b \) matrix written \( X \), where \( N_a \) is the number of frequency bands and \( N_b \) the total number of frames. In this study, we will consider the properties of another object, built from \( X \), which we call the Common Fate Transform (CFT). It is constructed as illustrated in Figure 1. We split the STFT \( X \) into overlapping rectangular \( N_a \times N_b \) patches, regularly spaced over both time and frequency. Then, the 2D-DFT of each patch is computed. This yields an \( N_a \times N_b \times N_f \times N_t \) tensor \( x \), where \( N_f \) and \( N_t \) are the vertical and horizontal positions for the patches, respectively.

As can be seen, the CFT is basically a further 2D-DFT taken over the standard STFT \( X \). One of the main differences compared to modulation spectrograms is that the CFT is computed using the complex STFT \( X \), and not a magnitude representation such as \(|X|\). As we will show, this simple difference has many interesting consequences, notably that the CFT is invertible: the original waveform \( \tilde{x} \) can be exactly recovered by first reconstructing the STFT \( X \), and then by cascading two classical overlap-add procedures. Another difference is that the patches span several frequency bins, i.e. we may have \( N_a > 1 \). This contrasts with the conventional modulation spectrogram, that is usually defined using one frequency band only.

2.2. A Probabilistic Model for the CFT

When processing an audio signal \( \tilde{x} \) for source separation, it is very common to assume that all time-frequency (TF) bins of its STFT are independent [23,26]. This is often the consequence of two different assumptions. The first one is to consider that all frames are independent, thus leading to the independence of all entries that do not belong to the same column. The second one is related to the notion of stationarity: roughly speaking, the Fourier transform is known to decompose stationary signals into independent components, whether these signals be Gaussian (see, e.g. [26]) or, more generally, harmonisable α-stable [27]. As a consequence, when the signals are assumed to be locally stationary, it is theoretically sound to assume that all the entries of their STFT are independent.

Still, both assumptions can only be considered as approximations. First, adjacent frames are obviously not independent, notably because of the overlap between them. Second, the stationarity assumption is only approximate in practice, especially when impulsive elements are found in the audio, leading to strong dependencies among the different frequency bins. Let \( \{X_{ft}\}_{f,t} \) denote all the \( N_a \times N_b \) patches taken on the STFT to compute the CFT, as depicted in Figure 1. The probabilistic model we choose is the combination of four different assumptions made on the distribution of these patches.

1. All patches are independent. Just as the classical locally stationary model [26] assumes independence of overlapping frames, we assume here independence of overlapping patches. Due to the overlap between them, this assumption is an approximation, and one may wonder what the advantage is of dropping independent frames for independent patches. The answer lies in the fact that the latter permits us to model phase dependencies between neighbouring STFT entries, and also to model much longer-term dependencies, as required for instance by deterministic damped or frequency-modulated sinusoidal signals.

2. Each patch is stationary, which means that its distribution is invariant under translations in the TF plane. Therefore, dependencies are to be expected among neighbouring STFT entries, in a way that only depends on their relative positions in the TF plane. It can easily be shown that mixtures of damped sinusoids have this property, just like in the HR-NMF model. Assuming stationarity not only over time but over both time and frequency also permits us to naturally account for mixtures of frequency-modulated sounds. The main relaxation of HR-NMF brought by our model lies in this assumption, that amounts to assuming independent and identically distributed (i.i.d.) innovations for one given patch, whereas the much more powerful HR-NMF model permits heteroscedastic innovations. This corresponds to assuming that throughout each patch, we observe one coherent STFT “texture”, whereas HR-NMF is able to handle more variability. However, taking overlapping patches somehow compen-

---

Footnotes:
1. Since the waveform \( \tilde{x} \) is real, the Fourier transform of each frame is Hermitian. In the following, we assume that the redundant information has been discarded to yield the STFT.
2. Note that since each patch is complex, its 2D-DFT is not Hermitian, thus all its entries are kept.
sates for this limitation.

3. The joint distribution of all entries of each patch is $\alpha$-stable [28]. $\alpha$-stable distributions are the only ones that are stable under additions, i.e. such that sums of $\alpha$-stable random variables (r.v.) remain $\alpha$-stable. They notably comprise the Gaussian and Cauchy distributions as special cases when $\alpha = 2$ and $\alpha = 1$, respectively.

4. Each patch is harmonisable, i.e. is the inverse Fourier transform of a complex random measure with independent increments. In other words, all entries of the Fourier transform of each patch are assumed to be asymptotically independent, as the size of the patch gets larger. This rather technical condition, often tacitly made in signal processing studies, permits efficient processing in the frequency domain.

Under those four assumptions, all entries of the CFT $x$ are independent (assumptions [1] and [2]), and each one is distributed with respect to a complex isotropic $\alpha$-stable distribution, noted $S\alpha S_c$ (assumptions [3] and [4]):

$$x(a, b, f, t) \sim S\alpha S_c\left(P^\alpha(a, b, f, t)\right),$$

where $P^\alpha$ is a nonnegative $N_a \times N_b \times N_f \times N_t$ tensor that we call the modulation density. When $\alpha = 2$, (1) corresponds to the classical isotropic complex Gaussian distribution and the entries of $P^\alpha$ are homogeneous to variances. In the general case, it can basically be understood as the energy found at $(a, b)$ for patch $(f, t)$, just like more classical (fractional) power spectral densities describe the spectro-temporal energy content of the STFT of a locally stationary signal.

2.3. Signal Separation

Now, let us assume that the observed waveform is actually the sum of $J$ underlying sources $\{s_j\}_{j=1}^{J}$. Due to the linearity of the CFT, this can be expressed in the CFT domain as:

$$\forall (a, b, f, t), x(a, b, f, t) = \sum_j s_j(a, b, f, t).$$

If we adopt the $\alpha$-stable model presented above for each source and use the stability property, we have:

$$x(a, b, f, t) \sim S\alpha S_c\left(\sum_j P^\alpha_j(a, b, f, t)\right),$$

where $P^\alpha_j$ is the modulation density for source $j$. If these objects are known, it can be shown that each source can be estimated in a maximum a posteriori sense from the mixture as:

$$\mathbb{E}\left[s_j(a, b, f, t) \mid \{P^\alpha_j\}, x\right] = \frac{P^\alpha_j(a, b, f, t)}{\sum_j P^\alpha_j(a, b, f, t)} x(a, b, f, t)$$

which we call the fractional $\alpha$-Wiener filter in [27]. The resulting waveforms are readily obtained by inverting the CFT. As can be seen, we now need to estimate the modulation densities $\{P^\alpha_j\}$ based on the observation of the mixture CFT $x$, similarly to the estimation of the sources’ (fractional) Power Spectral Densities ($\alpha$-PSD) in source separation studies.

Algorithm 1: Fitting NMF parameters of the nonnegative CFM (3).

With $v^\alpha = |x|^\alpha$ and always using the latest parameters available for computing $\hat{P}^\alpha_j(a, b, f, t) = \sum_j A_j(a, b, f) H_j(t)$, iterate:

$$A_j(a, b, f) \leftarrow A_j(a, b, f) \sum\sum_{a,b,f,t} v^\alpha(a,b,f,t) P^\alpha(a,b,f,t) \frac{(\beta - 2) \beta_j(a,b,f)}{\sum_{a,b,f} P^\alpha(a,b,f,t) \frac{(\beta - 2)}{\sum_{a,b,f} P^\alpha(a,b,f,t) \frac{(\beta - 2)}}A_j(a,b,f)}.$$  

2.4. Factorization Model and Parameter Estimation

In order to estimate the sources’ modulation densities, we first impose a factorization model over them, so as to reduce the number of parameters to be estimated. In this study, we set:

$$P^\alpha_j(a, b, f, t) = A_j(a, b, f) H_j(t),$$

where $A_j$ and $H_j$ are $N_a \times N_b \times N_f$ and $N_t \times 1$ nonnegative tensors, respectively. We call this a Common Fate Model. Intuitively, $A_j$ is a modulation density template that is different for each frequency band $f$, and that captures the long term modulation profile of source $j$ around that frequency. Then, $H_j$ is an activation vector that indicates the strength of source $j$ on the patches located at temporal position $t$. Learning those parameters can be achieved using the conventional Nonnegative Matrix Factorization methodology (NMF; see e.g. [25, 29, 30] for an overview and [31] for the fitting of $S\alpha S_c$ parameters), except that it is applied to the CFT instead of the STFT, and that the particular factorization to be used is (4).

Due to space constraints, we cannot detail the derivations of the fitting strategy. In essence, it amounts to estimating the parameters $\{A_j, H_j\}$ so that the modulus of the CFT, raised to the power $\alpha$, is as close as possible to $\sum_j P^\alpha_j$, with some particular cost function as a data-fit criterion, called a $\beta$-divergence and which includes Euclidean, Kullback-Leibler and Itakura-Saito as special cases [32]. As usual in such nonnegative models, each parameter is updated in turn, while the others are kept fixed.

We provide the multiplicative updates in Algorithm 1. After a few iterations, the parameters can be used in (3) to separate the sources.

3. EXPERIMENTS

In this section, we present separation experiments utilizing CFM and we compare it with other methods.

3.1. Synthetic Example

To illustrate the CFT representation we processed a mixture consisting of two sinusoidal sources. One source is a pure sine wave of fundamental frequency 440 Hz whereas the other is frequency modulated by a sinusoid of 6.3 Hz. In the first step an STFT with a DFT-length of 1024 samples and a hop-size of 256 samples was processed at a sample rate of 22.05 kHz. Patches of size $(N_a, N_b) = (32, 48)$ (not respecting overlaps) were then taken from the STFT output. Figure 2 in Section 2.1 then shows the Common Fate Transform for the mixture as described in Section 2. One can see that the CFT representation shows distinct patterns across time so that the factorization is able to separate the sources.
3.2. Objective Evaluation on Unison Instrument Mixtures

For an evaluation of the method, we selected five musical instruments’ samples, all featuring vibrato: violin, cello, tenor sax, English horn, and flute. It is important to note that vibrato techniques differ between instruments: whereas the English horn and the flute only produce a very subtle modulation, the violin and tenor sax have powerful frequency modulations with a higher modulation frequency as well as a higher modulation index. The signals have each been generated by rendering C4 (261.63 Hz) notes in a state-of-the-art software sample. All samples last about three seconds. The five instruments then generated a combination of ten mixtures of two instruments each. Each mixture is generated by a simple SourceA — SourceB — (SourceA + SourceB) scheme. Data were encoded in 44.1 kHz / 16 bit.

For the CFM model an STFT of DFT-length 1024 and a hop-size of 512 samples has been calculated. The resulting complex spectrogram was then split into a grid of patches of size \( (N_a, N_b) = (4, 64) \), each having a half-window overlap in both dimensions. For all experiments \( \alpha \) and \( \beta \) were set to 1. We chose to include other additional methods for our evaluation: we implemented a modified version of \([16]\) (MOD) where for the sake of comparability, we used a STFT instead of a gammatone filterbank. A DFT length of 1024 and a hop-size of 512 samples were chosen. After taking the magnitude value, a second STFT of size 32 and hop-size 16 samples was computed. We selected patch sizes of \( (N_a, N_b) = (1, 64) \) and modified the representation so that the magnitude spectrogram was used before computing the 2D-DFT. That way, our tensor representation with 1-bin-sized patches is close to \([16]\) while we still use the CFM factorization. This method is labelled as CFMMOD. Furthermore, the influence of the magnitude spectrogram alone while taking the (larger) CFM patches leads to a method referred to as CFMM. When comparing the methods mentioned above with a standard NMF based method \([4]\), note that a spectrogram computed by a DFT of length 1024 would not make a fair comparison since the CFM model actually results in a larger frequency resolution. Therefore a comparable NMF is based on an STFT of DFT-length 32768. An overview of the compared methods is listed in Table 1. All factorizations ran for 100 iterations and were repeated five times.

The results of CFMM indicate that the complex CFT lead to better results. NMF did perform surprisingly well, which may only hold for our test set, where each source is active for a long period. This results in a cyclic stationary vibrato, revealing spectral side lobes at such a high resolution. With more than one component per source, the results of CFM do improve, but it can be seen that more than two components \( (j = 4) \) will not increase the SDR values. The separation results and a full Python implementation of the CFM algorithm can be found on the companion website for this paper.

4. CONCLUSION

In this work we presented a method to exploit common modulation textures for source separation. A transformation based on a complex tensor representation computed from patches of the STFT has been introduced. We then showed how these patches are factorized by the proposed Common Fate Model, which is derived from the idea of humans perceiving common modulation over time as one source. Our results on unisonous musical instruments indicate that this method can perform well for this scenario. The CFM model could also be successfully used in other scenarios, such as speech separation.
