Abstract

In this paper we provide a formal justification of the use of time-frequency reassignment techniques on time-frequency transforms of discrete time signals. State of the art techniques indeed rely on formulae established in the continuous case which are applied, in a somehow inaccurate manner, to discrete time signals. Here, we formally derive a general framework for discrete time reassignment. To illustrate its applicability and generality, this framework is applied to a specific transform: the Constant-Q Transform.

Keywords: Reassigned time-frequency representations, reassigned CQT, discrete signals, synchrosqueezing

1. Introduction

Time-frequency reassignment has received great attention over the last decades, especially for the task of sinusoidal parameter estimation in noisy data. Numerous methods have been developed based on Fourier analysis [1, 2, 3],
5 on subspace decomposition [4, 5] or on more general models such as AM/FM models [6, 7]. Time-frequency reassignment methods aim at providing enhanced time-frequency representations with an improved resolution in both time and frequency. To this end, these methods propose to assign the energy computed at

*Corresponding author, e-mail address: Sebastien.Fenet@Zoho.com

some time-frequency point in the signal to a different point in the time-frequency
10 plane that depends on the window used for the spectral computation.

Time-frequency reassignment methods emerge from the idea first proposed
by Kodera [8]. This original approach uses the phase information of the time-
frequency representation and remains difficult to use in practice. Later on,
Auger and Flandrin [1] proposed a new closed-form solution to this problem
15 which applies to a wide variety of time-frequency representations and relies on
much more straightforward computations of the reassigned indexes. This work
has opened the door to the use of time-frequency reassignment in numerous
domains such as physics [9], radar imaging [10] or audio [11]. It has also led to
the development of numerous extensions and adaptations of the original method
20 [12, 13, 14].

Another solution to the problem, named *synchrosqueezing*, has been pro-
posed by Daubechies and Maes in [15]. Notably because it offers the ability
to reconstruct the time signals, the technique has drawn a lot of interest and
has become the root of multiple applications and enhancements [16, 17, 18] .
25 Although synchrosqueezing was initially presented as a distinct technique from
Auger and Flandrin's reassignment method, the strong connection that exists
between the two has been clarified in [19].

Traditionally, reassignment calculations are carried out in the context of
continuous time signals (see [20] for a review) while most applications involve
30 discrete time signals. In practice, all results obtained in the continuous time
case are applied, without detailed justification, to the discrete case.

In this work, we propose a formal framework for the computation of the re-
assigned transforms which fully takes into account the discrete time aspect. Our
approach consists of expressing the magnitude of the time-frequency transform
35 of a discrete signal as a mass function in the time-frequency plane and in assign-
ing the energy to the centre of mass of this representation. Interestingly, the
obtained mathematical expressions are very similar to the classical expressions
proved in the continuous time case. The main advantage of our approach is that
we obtain exact expressions of the solution when discrete signals are considered.

40 This opens the door to the implementation of exact solutions and, should the implementation require an approximate solution, we are able to characterise the introduced error. To some extent, this work also gives a formal justification of the common approximation made when applying continuous time formulae to discrete time signals.

45 The paper is organised as follows. The mathematical model and the derivations of closed-form expressions for reassigned time and frequency indexes are provided in section 2. We then discuss in the subsequent section the merit of the proposed solution. An application of the framework to a specific time-frequency representation, the Constant Q Transform (CQT), is finally proposed
50 in section 4.

2. Mathematical model

2.1. Traditional time-frequency representations

As stated in the introduction, our aim is to derive the mathematical formulation of the reassigned time-frequency representation of a discrete numerical
55 signal. We thus consider a discrete time signal x . Such a signal maps any discrete index $n \in \mathbb{Z}$ to a complex value $x_n \in \mathbb{C}$. Its frequency content $X(\xi)$ is defined for any normalised frequency $\xi \in \mathbb{R}/\mathbb{Z}$ by the Discrete Time Fourier Transform (we use the standard notation \mathbb{R}/\mathbb{Z} to indicate that the normalised frequency is defined modulo 1).

60 The information that one reads in a time-frequency representation of x is the amount of energy in x at time $t \in \mathbb{R}$ and normalised frequency $\nu \in [0; 1]$. In order to evaluate this energy, the scalar product between x and a kernel is computed. The kernel consists of a windowing sequence $h^{t,\nu}$, centred on t , multiplied by the harmonic function of frequency ν . Let us note that the (t, ν)
65 exponent makes it explicit that the windowing sequence depends on the time of interest and may also depends on the frequency of interest. More precisely, the transforms of x that fall within the scope of this paper can be written in the

following form:

$$\mathcal{T}^{x,h^{t,\nu}}(t,\nu) = \sum_{n \in \mathbb{Z}} h_n^{t,\nu} x_n e^{-j2\pi\nu n} \quad (1)$$

The time-frequency representation at time t and frequency ν is finally obtained
 70 by considering the squared magnitude of the transform:

$$s(t,\nu) = |\mathcal{T}^{x,h^{t,\nu}}(t,\nu)|^2. \quad (2)$$

It is interesting here to recall the Heisenberg-Gabor limit [21] that constrains the design of the windowing sequence $h^{t,\nu}$. More precisely, the Gabor limit states that there is a trade-off between the temporal and spectral resolutions when representing a signal in the time-frequency plane. In practice, adjusting
 75 the support of the windowing sequence is a direct way to tune this trade-off. A wide support will result in a precise frequency resolution with a poor temporal resolution. Conversely, a narrow support will provide a good temporal resolution at the cost of the frequency resolution. In order to ensure consistency, we consider that the windowing sequences are of finite support and that they are
 80 normalised by the size of their supports. For instance, h being a continuous window function of finite temporal support, the windowing sequence is defined by $h_n^{t,\nu} = h(n-t)$ in the case of a short-term Fourier Transform (STFT) or by $h_n^{t,\nu} = \nu h(\nu(n-t))$ in the case of a constant-Q Transform (CQT) for a set of frequencies ν within $[0; \frac{1}{2}]$ (see Section 4 for more details).

85 In addition to constraining the design of the window, the choice of a given time-frequency transform also determines the set of time-frequency points (t,ν) at which the representation is evaluated. Typically, a Short-Time Fourier Transform with a temporal hop size Δ_t and a spectral hop size Δ_ν is obtained with the following set of points: $\{(t_0 + k\Delta_t, \nu_0 + k'\Delta_\nu) \text{ for } (k,k') \in \mathbb{N}^2\}$. In contrast, the Constant-Q Transform, whose spectral geometric progression is often
 90 denoted by $2^{\frac{1}{r}}$ (r being the number of bins per octave), is obtained with the set $\{(t_0 + k\Delta_t, \nu_0 2^{\frac{1}{r}k'}) \text{ for } (k,k') \in \mathbb{N}^2\}$. In these expressions, t_0 naturally denotes the lowest time index of the representation and ν_0 the lowest frequency bin.

Let us make explicit here that in the following derivations we will be using

95 the notation \bar{z} for the complex conjugate of z and the symbol $*$ for the discrete convolution operator.

2.2. Time-frequency representations as mass functions

Reassignment techniques rely on the idea that time-frequency representations, at a given point (t, ν) , can be written as the sum of a mass function
 100 defined on the time-frequency plane (n, ξ) . Given our context, which involves a discrete time axis and a periodic frequency axis, we have $(n, \xi) \in \mathbb{Z} \times (\mathbb{R}/\mathbb{Z})$. We thus look for an expression of the form:

$$s(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi = \nu - \frac{1}{2}}^{\nu + \frac{1}{2}} \Phi^{t, \nu}(n, \xi) d\xi \quad (3)$$

where the function $\Phi^{t, \nu}$ is real-valued.

Let us define W , a discrete version of Rihaczek's ambiguity function [22], for
 105 any sequence $\varphi \in \ell^1(\mathbb{Z})$, time index $n \in \mathbb{Z}$ and frequency $\xi \in \mathbb{R}/\mathbb{Z}$ by:

$$W_\varphi(n, \xi) = \sum_{\tau \in \mathbb{Z}} \varphi_{n+\tau} \overline{\varphi_n} e^{-j2\pi\xi\tau}. \quad (4)$$

Proposition 1. *The time-frequency representation $s(t, \nu)$ of a discrete time signal $x \in \ell^1(\mathbb{Z})$, as defined in equation (2), can be written as the sum of a mass function, as in equation (3), with:*

$$\Phi^{t, \nu}(n, \xi) = \Re \left\{ W_{h^{t, \nu}}(n, \nu - \xi) W_x(n, \xi) \right\}.$$

Putting things together, this means that the time-frequency representation of x at point (t, ν) can be written in the following form:

$$s(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi = \nu - \frac{1}{2}}^{\nu + \frac{1}{2}} \Re \left\{ W_{h^{t, \nu}}(n, \nu - \xi) W_x(n, \xi) \right\} d\xi \quad (5)$$

PROOF. Let us evaluate the following expression:

$$E(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi = \nu - \frac{1}{2}}^{\nu + \frac{1}{2}} W_{h^{t, \nu}}(n, \nu - \xi) W_x(n, \xi) d\xi.$$

We have:

$$E(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \left\{ \sum_{\tau_1 \in \mathbb{Z}} h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} e^{-j2\pi(\nu-\xi)\tau_1} \sum_{\tau_2 \in \mathbb{Z}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\xi\tau_2} \right\} d\xi.$$

Knowing that $h^{t, \nu}$ is of finite support and that x is in $\ell^1(\mathbb{Z})$, Fubini's theorem ensures that the summations can be permuted:

$$E(t, \nu) = \sum_{n, \tau_1, \tau_2 \in \mathbb{Z}} \left\{ h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\nu\tau_1} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} e^{-j2\pi\xi(\tau_2-\tau_1)} d\xi \right\}.$$

Knowing that, for any integer k , we have:

$$\int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} e^{-j2\pi\xi k} d\xi = \begin{cases} 1 & \text{if } k = 0 \\ 0 & \text{otherwise} \end{cases}$$

the above expression can be rewritten with respect to a single shift variable τ :

$$E(t, \nu) = \sum_{n, \tau \in \mathbb{Z}} h_{n+\tau}^{t, \nu} \overline{h_n^{t, \nu}} x_{n+\tau} \overline{x_n} e^{-j2\pi\nu\tau}.$$

By the substitution $\tau \mapsto m - n$ we get:

$$\begin{aligned} E(t, \nu) &= \sum_{n, m \in \mathbb{Z}} h_m^{t, \nu} \overline{h_n^{t, \nu}} x_m \overline{x_n} e^{-j2\pi\nu(m-n)} \\ &= \left\{ \sum_{m \in \mathbb{Z}} h_m^{t, \nu} x_m e^{-j2\pi\nu m} \right\} \overline{\left\{ \sum_{n \in \mathbb{Z}} h_n^{t, \nu} x_n e^{-j2\pi\nu n} \right\}} \\ &= |\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2. \end{aligned}$$

110 Altogether, we have proved that:

$$|\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2 = \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} W_{h^{t, \nu}}(n, \nu - \xi) W_x(n, \xi) d\xi. \quad (6)$$

By applying the real part operator on both sides of the above equality, using its linearity and knowing that $|\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|$ is real, we get:

$$|\mathcal{T}^{x,h^{t,\nu}}(t,\nu)|^2 = \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Re \left\{ W_{h^{t,\nu}}(n, \nu - \xi) W_x(n, \xi) \right\} d\xi.$$

□

We have thus proved that the time-frequency representation of x at a given
 115 time t and frequency ν , which we have defined as the squared magnitude of
 the transform, can be expressed as the sum of a real-valued function in the
 time-frequency plane. In accordance with the context of discrete time signals,
 we have a discrete time axis (leading to a discrete summation over the time
 index) and a continuous and periodic frequency axis (leading to a continuous
 120 and finite summation over the frequency variable). It is also interesting to note
 that the contributions of the window $h^{t,\nu}$ and the signal x are quite separated
 and symmetric. They are induced through the same transform W that applies
 separately on the window and on the signal. We may now consider the function
 that is summed as a mass function and, as such, look for its centre of mass in
 125 the time-frequency plane.

2.3. Reassigned time index

Given the formulation (3) of the time-frequency representation at point (t, ν)
 as the two-dimensional sum of a mass function, it is possible to evaluate the
 centre of mass of this distribution in the time-frequency plane. By definition,
 130 the first coordinate of the centre of mass is given by the following formula:

$$\hat{t}^{t,\nu} = \frac{\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} n \Phi^{t,\nu}(n, \xi) d\xi}{\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Phi^{t,\nu}(n, \xi) d\xi}. \quad (7)$$

Proposition 2. *The temporal coordinate of the centre of mass in the time-frequency plane of the time-frequency representation evaluated at point (t, ν) , defined in equation (7), can also be expressed as:*

$$\hat{t}^{t,\nu} = t + \Re \left\{ \frac{\mathcal{T}^{x, r^t h^{t,\nu}}(t, \nu)}{\mathcal{T}^{x, h^{t,\nu}}(t, \nu)} \right\} \quad (8)$$

where r^t is the unit ramp centred on t : $r_n^t = n - t$.

135 PROOF. Let us evaluate the following quantity:

$$E'(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} n \Phi^{t, \nu}(n, \xi) d\xi. \quad (9)$$

We have:

$$E'(t, \nu) = \Re \left\{ \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \sum_{\tau_1 \in \mathbb{Z}} n h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} e^{-j2\pi(\nu-\xi)\tau_1} \sum_{\tau_2 \in \mathbb{Z}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\xi\tau_2} d\xi \right\}.$$

By using the same grouping and the same substitution as in the proof of Proposition 1, the expression becomes:

$$E'(t, \nu) = \Re \left\{ \sum_{n, m \in \mathbb{Z}} n h_m^{t, \nu} \overline{h_n^{t, \nu}} x_m \overline{x_n} e^{-j2\pi\nu(m-n)} \right\}.$$

Expanding n as $t + n - t$, we have:

$$\begin{aligned} E'(t, \nu) &= t \Re \left\{ \overline{\sum_{n \in \mathbb{Z}} h_n^{t, \nu} x_n e^{-j2\pi\nu n}} \sum_{m \in \mathbb{Z}} h_m^{t, \nu} x_m e^{-j2\pi\nu m} \right\} \\ &\quad + \Re \left\{ \overline{\sum_{n \in \mathbb{Z}} (n-t) h_n^{t, \nu} x_n e^{-j2\pi\nu n}} \sum_{m \in \mathbb{Z}} h_m^{t, \nu} x_m e^{-j2\pi\nu m} \right\} \end{aligned}$$

140 This can be more concisely written as:

$$E'(t, \nu) = t |\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2 + \Re \left\{ \overline{\mathcal{T}^{x, r^t h^{t, \nu}}(t, \nu)} \mathcal{T}^{x, h^{t, \nu}}(t, \nu) \right\} \quad (10)$$

Given the definitions (7) and (9), we know that dividing $E'(t, \nu)$ by $\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Phi^{t, \nu}(n, \xi) d\xi$ yields $\hat{t}^{t, \nu}$. Besides, we know from equations (2) and (3) that:

$$\begin{aligned} \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Phi^{t, \nu}(n, \xi) d\xi &= |\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2 \\ &= \mathcal{T}^{x, h^{t, \nu}}(t, \nu) \overline{\mathcal{T}^{x, h^{t, \nu}}(t, \nu)}. \end{aligned} \quad (11)$$

Thus, dividing equation (10) by $\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Phi^{t, \nu}(n, \xi) d\xi$, we finally get:

$$\hat{t}^{t, \nu} = t + \Re \left\{ \frac{\mathcal{T}^{x, r^t h^{t, \nu}}(t, \nu)}{\mathcal{T}^{x, h^{t, \nu}}(t, \nu)} \right\}$$

145

□

Let us recall that we are currently looking for the centre of mass of the mass function $\Phi^{t,\nu}$ from which the time-frequency representation $s(t, \nu)$ stems. What we have done here is establishing a simple expression of the time coordinate $\hat{t}^{t,\nu}$ of the centre of mass. The original definition of the centre of mass, shown in
150 equation (7), indeed leads to quite complex computations while our calculations have showed that the time coordinate of the centre of mass can be expressed mostly as the division of two transforms. The benefits of this expression will be further discussed in section 3 but it is already remarkable that we could express this coordinate in a nice and simple way.

155 2.4. Reassigned frequency

Similarly to what has been done for the time coordinate, the expression of the time-frequency representation at point (t, ν) as the sum of a mass function $\Phi^{t,\nu}$, proved in Proposition 1, allows to determine the frequency coordinate of the centre of mass of $\Phi^{t,\nu}$. The latter is defined by:

$$\hat{\nu}^{t,\nu} = \frac{\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \xi \Phi^{t,\nu}(n, \xi) d\xi}{\sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \Phi^{t,\nu}(n, \xi) d\xi} . \quad (12)$$

160 **Proposition 3.** *The frequency coordinate of the centre of mass in the time-frequency plane of the time-frequency representation evaluated at point (t, ν) , defined in equation (12), can also be expressed as:*

$$\hat{\nu}^{t,\nu} = \nu - \frac{1}{2\pi} \Im \left\{ \frac{\mathcal{T}^{x, h^{t,\nu}} * g(t, \nu)}{\mathcal{T}^{x, h^{t,\nu}}(t, \nu)} \right\} \quad (13)$$

where g is the differentiator filter, i.e. $g_n = \frac{(-1)^n}{n}$ for $n \neq 0$ and $g_0 = 0$.

PROOF. Let us evaluate the following expression:

$$E''(t, \nu) = \sum_{n \in \mathbb{Z}} \int_{\xi=\nu-\frac{1}{2}}^{\nu+\frac{1}{2}} \xi \Phi^{t,\nu}(n, \xi) d\xi . \quad (14)$$

165 We have:

$$E''(t, \nu) = \Re \left\{ \sum_{n \in \mathbb{Z}} \int_{\xi = \nu - \frac{1}{2}}^{\nu + \frac{1}{2}} \xi \sum_{\tau_1 \in \mathbb{Z}} h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} e^{-j2\pi(\nu - \xi)\tau_1} \sum_{\tau_2 \in \mathbb{Z}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\xi\tau_2} d\xi \right\}.$$

By the substitution $\xi \mapsto \xi' + \nu$ we get:

$$\begin{aligned} E''(t, \nu) &= \nu |\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2 \\ &+ \underbrace{\Re \left\{ \sum_{n \in \mathbb{Z}} \int_{\xi' = -\frac{1}{2}}^{\frac{1}{2}} \xi' \sum_{\tau_1 \in \mathbb{Z}} h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} e^{j2\pi\xi'\tau_1} \sum_{\tau_2 \in \mathbb{Z}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi(\xi' + \nu)\tau_2} d\xi' \right\}}_{E_2''(t, \nu)}. \end{aligned}$$

In the above expression, let us call the second operand $E_2''(t, \nu)$. We now have:

$$E''(t, \nu) = \nu |\mathcal{T}^{x, h^{t, \nu}}(t, \nu)|^2 + E_2''(t, \nu). \quad (15)$$

Adequately reordering the summations in $E_2''(t, \nu)$, the latter can be written as:

$$E_2''(t, \nu) = \Re \left\{ \sum_{n, \tau_1, \tau_2 \in \mathbb{Z}} h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\nu\tau_2} \int_{\xi' = -\frac{1}{2}}^{\frac{1}{2}} \xi' e^{j2\pi\xi'(\tau_1 - \tau_2)} d\xi' \right\}.$$

Let us define the sequence g in the following way:

$$g_n = \int_{\xi' = -\frac{1}{2}}^{\frac{1}{2}} 2j\pi\xi' e^{j2\pi\xi'n} d\xi' = \begin{cases} \frac{(-1)^n}{n} & \text{if } n \neq 0 \\ 0 & \text{if } n = 0 \end{cases}. \quad (16)$$

170 The expression of $E_2''(t, \nu)$ consequently becomes:

$$E_2''(t, \nu) = \Re \left\{ \frac{j}{2\pi} \sum_{n, \tau_1, \tau_2 \in \mathbb{Z}} h_{n+\tau_1}^{t, \nu} \overline{h_n^{t, \nu}} x_{n+\tau_2} \overline{x_n} e^{-j2\pi\nu\tau_2} g_{\tau_2 - \tau_1} \right\}.$$

We can then use the substitution:

$$\begin{cases} \tau_2 & \mapsto l - n \\ \tau_1 & \mapsto l - n - m \end{cases}$$

to get the following equation.

$$E_2''(t, \nu) = \Re \left\{ \frac{j}{2\pi} \sum_{n, m, l \in \mathbb{Z}} h_{l-m}^{t, \nu} \overline{h_n^{t, \nu}} x_l \overline{x_n} e^{-j2\pi\nu(l-n)} g_m \right\}.$$

As far as the terms in m are concerned, we observe that:

$$\sum_{m \in \mathbb{Z}} h_{l-m}^{t,\nu} g_m = (h^{t,\nu} * g)_l .$$

The whole expression can thus be rewritten:

$$E_2''(t, \nu) = \Re \left\{ \frac{j}{2\pi} \sum_{n \in \mathbb{Z}} \overline{h_n^{t,\nu}} x_n e^{-j2\pi\nu n} \sum_{l \in \mathbb{Z}} (h^{t,\nu} * g)_l x_l e^{-j2\pi\nu l} \right\} .$$

By identifying the transforms in the above expression of $E_2''(t, \nu)$ and reinjecting in equation (15), we get:

$$E''(t, \nu) = \nu |\mathcal{T}^{x,h^{t,\nu}}(t, \nu)|^2 - \frac{1}{2\pi} \Im \left\{ \overline{\mathcal{T}^{x,h^{t,\nu}}(t, \nu)} \mathcal{T}^{x,h^{t,\nu} * g}(t, \nu) \right\} .$$

175 Taking into account equation (11) and given the definition (14) of $E''(t, \nu)$, it is only needed to divide the latter by $|\mathcal{T}^{x,h^{t,\nu}}(t, \nu)|^2$ to obtain $\hat{\nu}^{t,\nu}$, as defined in equation(12). This finally leads to:

$$\hat{\nu}^{t,\nu} = \nu - \frac{1}{2\pi} \Im \left\{ \frac{\mathcal{T}^{x,h^{t,\nu} * g}(t, \nu)}{\mathcal{T}^{x,h^{t,\nu}}(t, \nu)} \right\}$$

□

Similarly to what we have done in Section 2.3 for the time coordinate, we
 180 have obtained here a simple expression of the frequency coordinate of the centre of mass of $\Phi^{t,\nu}(n, \xi)$. Although the mathematical steps that led to this expression are rather different from the ones performed in the case of the first coordinate, the final result in equation (13) is quite symmetric with the one in equation (8). In a similar fashion, the frequency coordinate is expressed as a
 185 simple combination of two transforms. This expression of $\hat{\nu}^{t,\nu}$ will be further discussed in the next section.

3. Discussion

In the previous section, we have obtained exact expressions of the coordinates $(\hat{t}^{t,\nu}, \hat{\nu}^{t,\nu})$ of the centre of mass of $\Phi^{t,\nu}$. The latter is a mass function

190 whose summation in the time frequency plane gives $s(t, \nu)$ *i.e.* the value of the
time-frequency representation of x at time t and frequency ν . The obtained
expressions are valid for any time-frequency representation of a discrete signal
with any kind of windowing. Time-frequency reassignment consists of building
an enhanced time-frequency representation of x simply by reassigning the value
195 $s(t, \nu)$ to the time-frequency point $(\hat{t}^{t,\nu}, \hat{\nu}^{t,\nu})$.

3.1. Practical interest of the expressions

The major advantage of the presented formulae for $\hat{t}^{t,\nu}$ and $\hat{\nu}^{t,\nu}$ is that they
provide a way of computing the reassigned index with the computation of only
three transforms, one of which is the ‘original’ one ($\mathcal{T}^{x,h^{t,\nu}}(t, \nu)$). The presented
200 reassignment tool is thus very powerful since it only involves an increase of the
computation time by a factor 3 compared to the original representation, which
does not seem a very high price to pay considering the tremendous gain of
resolution.

In detail, in order to compute the reassigned time index as in equation
205 (8), one has to compute an additional transform of x with a window function
which consists of the original window function multiplied by the unit ramp
function. The real part of the division of this ramp-windowed transform by the
original transform provides the time shift. In order to compute the reassigned
frequency index as in equation (13), one has to compute the transform of x with
210 a window sequence which is the original window convolved with some discrete
filter g . Let us note that this modified window can be pre-computed once so that
calculating the transform of x with this window has the same complexity as with
the original window. The frequency shift is proportional to the imaginary part
of the transform with the convolved window divided by the original transform.

3.2. Comparison with previously established expressions

The transition from the mathematical proof of the time-frequency reassign-
ment formulae in the context of continuous time signals [1] to the one for discrete
time signals is not straightforward. The continuous proof indeed relies on the

rewriting of the spectrogram as a summed product of Wigner-Ville transforms
220 [23, 24, 25]. However, since the Wigner-Ville transform involves non-integer
shifts, it cannot be directly applied to discrete-time signals. We have overcome
the issue by introducing in equation (4) the transform W , which can be seen
as a discrete version of Rihaczek's ambiguity function [22]. This transform is
225 fully applicable to discrete time signals but it lacks the symmetric design of
the Wigner-Ville transform. As a result, the transform is not bounded to real
values. Fortunately, we could still step back to the expression of a real-valued
mass function by applying the real operator on equation (6). Another pitfall
when switching to discrete time signals is the choice of ξ 's integration interval in
equation (3). Given the spectral periodicity of discrete signals, it is clear enough
230 that the interval should be of unit length. However, the localisation of the inter-
val is not obvious. It does not intervene in the calculation of the reassigned time
index but it has a meaningful impact when deriving the reassigned frequency
index. Our calculations have shown that, in a rather expectable and logical
way, the interval of integration should be centred around ν when studying the
235 time-frequency representation at point (t, ν) .

In spite of the meaningfully dissimilar calculations steps that led to them,
the formulae that we finally obtain for $\hat{t}^{t,\nu}$ and $\hat{\nu}^{t,\nu}$ are very similar to the ones
obtained in the continuous case by Auger and Flandrin [1]. The expression of
the reassigned time index is indeed the same, with the same appearance in the
240 calculation of the window multiplied by the ramp function. One meaningful con-
tribution of our work, though, is that our expressions have been derived in the
context of discrete time signals. There is thus no approximation when applying
it to real signals and we have formally proved that the expression is valid. As
far as the reassigned frequency index is concerned, the continuous proof, which
245 relies on an integration by parts, leads to an expression that brings the deriva-
tive of the original window into play. On the other hand, our calculations lead
to a new window which is the original one convolved with a filter g . For that
matter, it is very interesting to note that the filter g that we obtain is the ideal
differentiator filter. It is indeed clear in the definition of g , given in equation

250 (16), that it is the inverse Fourier Transform of $2j\pi\xi'$ which is the frequency
 response of the perfect differentiator. The similarity between our expression
 and the one from Auger and Flandrin then becomes clear. To some extent, we
 may indeed consider that the “derivative” of h approximates the convolution of
 h by g . We however take full advantage here of our discrete time approach. We
 255 indeed have an exact formulation for the reassigned frequency index whereas
 Auger and Flandrin propose to compute the “derivative” of h . The derivative is
 quite an ill-defined concept for discrete time signals and applying their formula
 raises the question of the best way to estimate it. Our work brings an answer
 to this, until now, open question. The technically correct way of using Auger
 260 and Flandrin formula is to estimate the derivative with an ideal differentiator
 filtering.

3.3. From reassignment to synchrosqueezing

As stated in the introduction the pioneering approach of Kodera [8] sug-
 gests to compute the reassigned time and frequency indexes by using the par-
 265 tial derivatives of the phase of the time-frequency representation. In a similar
 spirit, the synchrosqueezing method [15] makes use of the partial derivatives of
 the phase to compute the reassigned frequency index. A notable difference of
 synchrosqueezing, however, is that only the frequency index is reassigned.

Our method, on the other hand, looks for the centre of mass of the distribu-
 270 tion $\Phi^{t,\nu}$ related to the time-frequency representation $s(t, \nu)$. The equivalence
 between the computation of the reassigned indexes thanks to the partial deriva-
 tives of the phase and the computation of the same indexes through the centre
 of mass has however been proved in [1].

As a result, as explained in [19], the synchrosqueezing method can be com-
 275 puted within our framework in a straightforward way. First, the reassigned
 frequency $\hat{\nu}^{t,\nu}$ is determined according to equation (13). Finally, the *complex*
value $\mathcal{T}^{x,h^{t,\nu}}(t, \nu)$ is additively reassigned to the point $(t, \hat{\nu}^{t,\nu})$. The differences
 with the reassignment method that we detailed in the first place are thus clear

and limited: only the frequency index is reassigned and the reassignment is op-
erated on the complex value of the transform instead of its squared magnitude.

4. Application: A reassigned Constant-Q Transform

As explained, the formal framework derived above is valid for a wide variety of time-frequency transforms. To illustrate its applicability, we propose to demonstrate the merit of the reassignment strategy on the Constant-Q Transform. The interested reader will find a Python implementation of this reassigned Constant-Q Transform on the authors' homepages¹.

4.1. Presentation of the transform

The Constant-Q Transform is a common tool in the field of audio processing. Its numerous fields of application include main melody extraction [26], audio-fingerprinting [27], chords detection [28, 29]. It was first proposed in [30] by Brown, who aimed at designing a time-frequency representation that mimics our perception of sound. To this end, the Constant-Q Transform has frequency bins with geometrically spaced centre frequencies. Moreover, their frequency resolution is inversely proportional to the centre frequency. Its direct calculation, however, is computationally heavy compared to the Short Time Fourier Transform which can rely on the Fast Fourier Transform. Hence the proposition by Brown and Puckette of a faster implementation in [31] and a follow-up in [32] by Klapuri. Another pitfall of the initial transform is its non-invertibility. As a consequence, several authors have focused on designing an invertible version of the Constant-Q Transform [33, 34, 35, 36]. Very recently, the concept of reassigned Constant-Q Transform has appeared in [37] and [12]. The point of view is however slightly different from the one adopted here since both works present the Constant-Q Transform as an application example of the theory derived in [12]. In the latter, reassignment formulae are specifically derived for filter banks.

¹googledrive.com/host/0B1DUW3X2T63neXhKWmxrTW5nUIE/ressources.html

305 Since they rely on the work by Auger and Flandrin [1], the derivations are only carried out for continuous-time signals.

More precisely, in the context of the Constant-Q spectrogram, one evaluates the amount of energy in x at any time t for a set of frequencies $\{\nu_k\}$. The ν_k 's are distributed according to the following law:

$$\nu_k = 2^{\frac{k}{r}} \nu_0$$

The parameter r specifies the resolution of the transform (the bigger r is, the more numerous the frequency bins are) and ν_0 is the centre of the lowest frequency bin of the transform. A meaningful interest of the Constant-Q Transform
 310 is that the ν_k 's can be aligned on the note frequencies of the Western scale. The parameter r then corresponds to the number of bins per octave, or equivalently, $r/12$ to the number of bins per note.

As far as the windowing functions are concerned, the Constant-Q Transform scales them with respect to frequency:

$$h_n^{t,\nu} = \nu h(\nu(n - t))$$

where h is a window function. The above relationship implies that the temporal support of the window decreases as ν_k increases. This equivalently means
 315 that the temporal resolution of the transform increases with frequency, and, according to the Heisenberg-Gabor principle [21], that its frequency resolution decreases.

The results presented thereafter have been obtained with the following set of parameters:

$$\begin{cases} r = 36 \\ \nu_0 = 2.45 \times 10^{-3} \end{cases}$$

and h^{t,ν_0} is a Hann window whose length is about 22500 samples. The analysed sound has a sampling rate of 44100 Hz, which means that the lowest frequency
 320 bin of the transform corresponds to the continuous frequency 107.9 Hz and that the support of h^{t,ν_0} is half a second long. With this setup the frequency bins of the transform are aligned on the note frequencies of the Western scale,

Figure 1: Spectrogram of a piano sound, sampled at 44100 Hz, obtained by means of the traditional Constant-Q Transform. The X axis is the time, it is labelled with the integer indexes of the sampled signal. The Y axis represents the frequency. It is noticeable that the latter follows a logarithmic scale.

with a resolution of 3 bins per note. More specifically, the three lowest bins of the transform are centre on 110 Hz, which corresponds to the frequency of the musical note A_2 .

4.2. Considerations on the resolution

Figure 1 shows the spectrogram of a piano sound obtained by means of the traditional Constant-Q Transform. We can see that the frequency resolution of the transform is well adapted to the musical sound since every frequency of the sound is well resolved. As mentioned, this transform has a better frequency resolution in low frequencies, where the musical frequencies are closer to each other. Of course, the counterpart of this better frequency resolution is a loss in temporal resolution. As a result, in spite of the fact that all frequencies of the piano sound have been played simultaneously, one can observe in the spectrogram that the energy in low frequencies starts earlier than in the higher frequencies. Similarly, the energy in low frequencies vanishes later. This is a typical artifact of the Constant-Q Transform due to these resolution considerations.

Figure 2: Spectrogram of the same piano sound as in Figure 1 obtained by means of the reassigned Constant-Q Transform.

4.3. Application of the reassignment tool

It is quite straightforward to apply the reassignment formulae to the Constant-Q Transform. When evaluating the energy in x at time t and frequency ν_k , the process is the following. We first compute the magnitude of the Constant-Q Transform at (t, ν_k) . We then compute the Constant-Q Transform with the ramp-multiplied windows. We finally compute the Constant-Q Transform with the g -convolved windows. Thanks to equations (8) and (13), we obtain the indexes \hat{t}^{t, ν_k} and $\hat{\nu}^{t, \nu_k}$. In the end, the energy computed at point (t, ν_k) is additively reassigned to the point $(\hat{t}^{t, \nu_k}, \hat{\nu}^{t, \nu_k})$ in the time-frequency plane.

Figure 2 shows the reassigned Constant-Q Transform of the same piano sound as in Figure 1. One can see that the temporal resolution has much improved in the second figure. The typical artifacts of the widening energy bursts in low frequencies seem to be accurately handled in the reassigned spectrogram. Besides, one can see that the frequency resolution has also improved. Even if the original tool's design ensures a suitable frequency resolution for sound applications, we can observe that the reassigned transform has much more localised (in terms of frequency) energy bursts.

355 5. Conclusion

In this work we have derived a formal framework for the time-frequency reassignment of discrete time signals. The principle of time-frequency reassignment is to express the time-frequency transform of interest as the summation of a real-valued mass function in the time-frequency plane. The energy is then reas-
 360 signed to the centre of mass of this function. The first derivations carried out in this paper result in an explicit expression of the mass function which is valid for a wide variety of time-frequency transforms. Based upon the latter, an expression of the coordinates of the centre of mass could be obtained. Interestingly, it consists of very simple combinations of three time-frequency transforms, each of
 365 them using a specific window. This result makes time-frequency reassignment a rather generic, simple and easily computable technique.

To illustrate the applicability of the derived framework as well as the benefits of time-frequency reassignment, the obtained results have then been applied to the Constant-Q Transform. This transform, commonly used in audio processing,
 370 has geometrically-spaced frequency bins with a variable resolution. This makes it a well adapted tool for the analysis of sound. This frequency setup, however, comes at the cost of time resolution, which has the serious drawback of being variable with frequency. Once reassigned though, the representation provides a much better resolution, in time and frequency. A Python implementation
 375 of this enhanced tool is available on the authors' homepages². It is our belief that the proposed reassigned Constant-Q Transform has a strong potential for numerous audio processing applications, including pitch/multipitch estimation, onset detection and chords transcription.
